

6.1.4 Summary to: 6.1 Materials and Processes for Silicon Technology

- ▶ Making "metallurgical" (= "dirty") **Si_{met}** is easy: ⇒
 - A large scale **Si_{met}** production (> **1 Mio tons/a**) exists for metallurgical ("alloying") and chemical ("silicones") uses
- ▶ A small amount of **Si_{met}** (some **20.000 to/a**) is purified (factor **10⁹** or so) to "semiconductor grade **Si**" ⇒
 - Produce high-purity trichlorosilane (**SiHCl₃**) gas in a reactor and distill.
 - Use **SiHCl₃** and **H₂** to deposit **Si** on some **Si** core by a **CVD** process
- ▶ The final result is ultra-high purity (and expensive) **poly Si** (already doped if so desired)

- ▶ Growing a "perfect" single crystal from this **poly-Si** is not easy - but possible.
 - The major crystal growth method is the **CZ** (= Czochalski) method: "Pull" the crystal from a crucible full of molten **Si**. ⇒
 - Some (usually < **300 mm** diameter) crystals are grown by the **FZ** (= float zone) method. Somewhat better perfection, but more expensive than **CZ**.
- ▶ Major problem: Impurity segregation = general tendency for most impurities (including doping atoms) to remain (= enrich) in the melt.
 - Segregation coefficient = $c_{\text{cryst}}/c_{\text{melt}}$ at interface, often $\ll 1$ and dependent on parameters like growth speed (usually a few **mm/min**).
 - + Crystal is purer than melt.
 - It is practically impossible to grow a crystal with a uniform impurity (including dopant!) concentration along its length.

- ▶ Produce wafers by cutting, grinding and polishing
 - Extreme precision for a mass product is needed.
 - "Flats" or "notches" (for wafers > **200 mm**) identify the crystallographic orientation and the doping type.
 - Beware! Flats are often custom specific and different from the norm. ⇒
